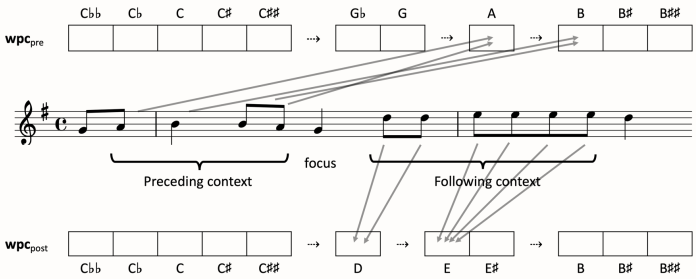
Aim. Design a flexible model of how to generate musically meaningful harmonic progressions to accompany a given melody. Rule-based, deterministic, explainable.

Step 1. Compute a **Weighted Pitch Context Vector** for each note.



The length of the context is a parameter. Here: the context extends till a note with a beatstrength of 1.0. The weight of each pitch is determined by its beatstrength and by its distance from the focus note.

Representation

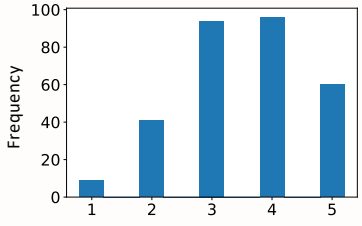
Step 2. Generate **candidate chords** (dim, Maj, min, Dom7) for each note, for preceding, following and full contexts and all possible root notes, and compute **a score for each candidate chord** based on the pitch context vector and the inferred local scale.

Step 3. Compute the **optimal path** through the candidate chords, using a dynamic programming algorithm and a chord transition score function.

The **chord transition score function** implements the desirable properties of chord transitions. Here: rules from tonal harmony.

Evaluation. We generated 50 harmonizations which were **rated by musical experts** on a five-point likert scale:

1. Bad. Numerous basic mistakes.
2. Somethings are good but contains a number of incorrect chord choices.
3. Largely okay, small number of incorrect chord choices.
4. Acceptable harmonization.
5. Excellent harmonization. No improvements to be made.



Distribution of scores
